Chapter 12: Marginal approaches to categorical data

Timothy Hanson

Department of Statistics, University of South Carolina

Stat 770: Categorical Data Analysis
Repeated measures

Example of repeated measures:

- Data are comprised of several repeated measurements on the same individual over time, e.g. $Y_{ij}$ might indicate an acne outbreak for patient $i$ in month $j$.
- Data are recorded in clusters, e.g. $Y_{ij}$ might indicate the presence of tooth decay for tooth $j$ in patient $i$.
- Data are from naturally associated groups, e.g. $Y_{ij}$ might denote a successful treatment of patient $j$ at clinic $i$.

In all of these examples, the repeated measurements are (typically positively) correlated within an individual or group.
12.2 Marginal GLM modeling of multiple categorical responses

Let $T_i$ binary responses $\mathbf{Y}_i = (Y_{i1}, \ldots, Y_{iT_i})$ come from the $i^{th}$ cluster (individual, litter, clinic, etc.) Let $\mathbf{\mu}_i = (\mu_{i1}, \ldots, \mu_{iT_i})$ where $\mu_{ij} = E(Y_{ij})$. Let $\mathbf{x}_{ij}$ be a $p \times 1$ vector of explanatory variables.

We assume the vectors $\mathbf{Y}_1, \ldots, \mathbf{Y}_n$ are independent, but that elements of $\mathbf{Y}_i$ are correlated. Common choices are

$$R(\alpha) = \text{corr}(\mathbf{Y}_i) = \begin{bmatrix} 1 & \alpha & \alpha & \cdots & \alpha \\ \alpha & 1 & \alpha & \cdots & \alpha \\ \alpha & \alpha & 1 & \cdots & \alpha \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \alpha & \alpha & \alpha & \cdots & 1 \end{bmatrix}_{T_i \times T_i}$$ exchangeable,

and $R(\alpha) = \text{corr}(\mathbf{Y}_i) = \begin{bmatrix} 1 & \alpha & \alpha^2 & \cdots & \alpha^{T_i-1} \\ \alpha & 1 & \alpha & \cdots & \alpha^{T_i-2} \\ \alpha^2 & \alpha & 1 & \cdots & \alpha^{T_i-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \alpha^{T_i-1} & \alpha^{T_i-2} & \alpha^{T_i-3} & \cdots & 1 \end{bmatrix}_{T_i \times T_i}$ AR(1).
Other correlation choices

\[ R(\alpha) = \text{corr}(Y_i) = \begin{bmatrix}
1 & \alpha_{12} & \alpha_{13} & \cdots & \alpha_{1T} \\
\alpha_{12} & 1 & \alpha_{23} & \cdots & \alpha_{2T} \\
\alpha_{13} & \alpha_{23} & 1 & \cdots & \alpha_{3T} \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
\alpha_{1T} & \alpha_{2T} & \alpha_{3T} & \cdots & 1 \\
\end{bmatrix}_{T \times T} \text{ unstructured,} \]

and \[ R = \text{corr}(Y_i) = \begin{bmatrix}
1 & 0 & 0 & \cdots & 0 \\
0 & 1 & 0 & \cdots & 0 \\
0 & 0 & 1 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & 1 \\
\end{bmatrix}_{T_i \times T_i} \text{ independence.} \]
You can also specify a fixed, known $R$ as well as $\text{MDEP}(m)$ which yields $R(\alpha)$ as

$$\text{corr}(Y_{ij}, Y_{i,j+t}) = \begin{cases} 
1 & t = 0 \\
\alpha_t & t = 1, \ldots, m \\
0 & t > m 
\end{cases}.$$ 

- Unstructured most general; often a default choice. However, need balance: $T_i = T$ for all $i$.
- Exchangeable useful when time is not important and correlations thought to be approximately equal, e.g. repeated measurements on individual in crossover study, measurements across several individuals from clinic $i$.
- $\text{AR}(1)$ useful when serial correlation plausible, e.g. repeated measurements across equally spaced time points on individual.
These correlation matrices are used in a GEE algorithm (sketched below) in PROC GENMOD.

Repeated measures are accounted for via REPEATED statement.

The order of \((Y_{i1}, \ldots, Y_{iT})\) makes a difference with some \(R(\alpha)\). If ordering is different to that defined in the DATA step, one can use the WITHIN subcommand in the REPEATED statement to tell SAS what the ordering is. Also used when missing some measurements in \((Y_{i1}, \ldots, Y_{iT})\).

CORRW in the REPEATED statement gives the final working correlation matrix estimate.

Elements of \(\beta\) are interpreted as usual, but *averaged over clusters*. This is a *marginal* interpretation.
Let $\mu_{ij} = g^{-1}(x'_{ij}\beta)$ be the marginal mean. We assume $Y_{ij}$ is from an exponential family

$$Y_{ij} \sim f(y_{ij}; \theta_{ij}, \phi) = \exp\left\{\frac{[y_{ij}\theta_{ij} - b(\theta_{ij})]}{\phi} + c(y_{ij}, \phi)\right\},$$

where the dispersion $\phi$ is known. The GEE approach requires some notation:

- $\mu_{ij} = b'(\theta_{ij})$ and $\nu(\mu_{ij}) = \text{var}(Y_{ij}) = b''(\theta_{ij})\phi$.
- $R(\alpha)$ is “working correlation matrix,” reflecting our best guess at the true correlation structure among the elements of $Y_i$. See the previous slide. Choice of $R(\alpha)$ can be made based on QIC (Pan, 2001).
- $B_i = \text{diag}(b''(\theta_{i1}), \ldots, b''(\theta_{iT}))$ is a diagonal matrix with $\text{var}(Y_{ij})/\phi$ along the diagonal.
- $V_i = B_i^{1/2}R(\alpha)B_i^{1/2}\phi$ is the working covariance matrix.
Let $\mathbf{D}_i = \frac{\partial \mu_i}{\partial \beta} = \mathbf{B}_i \mathbf{\Delta}_i \mathbf{X}_i$ be the $T_i \times p$ matrix of first partial derivatives where $\mu_i = \mu_i(\beta) = (g^{-1}(x'_{i1}\beta), \ldots, g^{-1}(x'_{iT_i}\beta))$, $\mathbf{\Delta}_i = \text{diag}(\frac{\partial \theta_{i1}}{\partial \eta_{iT_i}}, \ldots, \frac{\partial \theta_{i1}}{\partial \eta_{iT_i}})$, $\eta_{ij} = x'_{ij}\beta$, and $\mathbf{X}_i = \begin{bmatrix} x'_{i1} \\ \vdots \\ x'_{iT_i} \end{bmatrix}$.

The generalized estimating equations (GEE) are

$$u(\beta) = \sum_{i=1}^{n} \mathbf{D}_i' \mathbf{V}_i^{-1} [y_i - \mu_i(\beta)] = 0.$$ 

These correspond to likelihood (score) equations, but are not derived from a proper likelihood. However, the $\hat{\beta}$ that solves them is consistent, even when the correlation assumption is wrong. Roughly speaking, this is because consistency is a first moment (mean) property.
Basic idea

For correlated normal data where \( E(Y_i) = X_i \beta \) and \( \text{cov}(Y_i) = \Sigma_i \), the maximum likelihood estimate of \( \beta \) is

\[
\hat{\beta} = \left[ \sum_{i=1}^{n} X_i' \Sigma_i^{-1} X_i \right]^{-1} \sum_{i=1}^{n} X_i \Sigma_i^{-1} Y_i,
\]

which solves the score equations

\[
\sum_{i=1}^{n} X_i' \Sigma_i^{-1} (Y_i - X_i \beta) = 0.
\]

For our (uncorrelated) data, the score equations are

\[
\sum_{i=1}^{n} \left[ D_i' \right] \left[ B_i^{-1} (Y_i - \mu_i(\beta)) \right] = 0.
\]

GEE simply replaces \( B_i \) by \( V_i = B_i^{1/2} R(\alpha) B_i^{1/2} \). Note that \( V_i = \hat{\Sigma}_i \) in the correlated normal model.
Liang and Zeger (1986) show \( \hat{\beta} \sim N_p(\beta, V_G) \) where

\[
V_G = \left( \sum_{i=1}^{n} D_i' V_i^{-1} D_i \right)^{-1} \left( \sum_{i=1}^{n} D_i' V_i^{-1} \text{cov}(Y_i) V_i^{-1} D_i \right) \left( \sum_{i=1}^{n} D_i' V_i^{-1} D_i \right)^{-1}.
\]

Here \( \beta \) is replaced by \( \hat{\beta} \), \( \phi \) replaced with \( \hat{\phi} \) (\( \phi = 1 \) for binomial and Poisson models), and \( \alpha \) replaced by \( \hat{\alpha} \). \( \text{cov}(Y_i) \) is replaced by \( [y_i - \mu_i(\hat{\beta})][y_i - \mu_i(\hat{\beta})]' \).

This *sandwich estimator* sandwiches an empirical estimate between the theoretical (working guess) \( \left( \sum_{i=1}^{n} D_i' V_i^{-1} D_i \right)^{-1} \). If we know for certain (we don’t) that \( \text{corr}(Y_i) = R(\alpha) \), then we can use this instead (MODELSE in the REPEATED statement).
To reiterate, the ingredients for the marginal GEE approach are

- A marginal model where $Y_{ij}$ is binomial, Poisson, normal, gamma, etc. with mean $\mu_{ij} = g^{-1}(x_{ij}' \beta)$.

Note that often for repeated measures, $x_{ij} = x_i$ for $j = 1, \ldots, T_i$; e.g. gender and weight are not apt to change over a 6 month study.

- An assumption on how the elements of $Y_i = (Y_{i1}, \ldots, Y_{iT_i})$ are correlated, $\text{corr}(Y_i) = R(\alpha)$. 
Table 12.1 (p. 456) houses data from a longitudinal study comparing a new drug with a standard drug for treatment of subjects suffering mental depression. \( n = 340 \) Patients were either mildly or severely depressed upon admission into the study. At weeks 1, 2, and 4, corresponding to \( j = 1, 2, 3 \), patient \( i \)'s suffering \( Y_{ij} \) was classified as normal \( Y_{ij} = 1 \) or abnormal \( Y_{ij} = 0 \). Let \( s_i = 0, 1 \) be the severity of the diagnosis (mild, severe) and \( d_i = 0, 1 \) denote the drug (standard, new).

We treat time as a categorical predictor and fit a marginal logit model with an exchangeable correlation structure; note \( T = 3 \):

\[
\text{corr}(Y_i) = \text{corr} \left( \begin{bmatrix} Y_{i1} \\ Y_{i2} \\ Y_{i3} \end{bmatrix} \right) = \begin{bmatrix} 1 & \alpha & \alpha \\ \alpha & 1 & \alpha \\ \alpha & \alpha & 1 \end{bmatrix}.
\]
SAS code and output

data depress;
    infile "c:/tim/cat/depress.txt";
    input case diagnose treat time outcome; time=time+1;
proc genmod descending; class case time;
    model outcome = diagnose treat time treat*time / dist=bin link=logit type3;
    repeated subject=case / type=exch corrw;

Clearly, there is an important interaction between time and the treatment. The initial diagnosis is also important. Fitting two more models shows that there is no evidence of interaction between diagnosis and treatment or diagnosis and time.

We see a severe diagnosis ($s = 1$) significantly decreases the odds of a normal classification by a factor of $e^{-1.31} = 0.27$. The odds (for normal classification) ratio comparing the new drug to the standard drug changes with time because of the interaction. At 1 week it’s $e^{2.04-2.09} = 0.95$, and week 2 it’s $e^{2.04-1.10} = 2.6$, and at 4 weeks it’s $e^{2.04-0} = 7.7$. The new drug is better, but takes time to work.
Here, the focus is on whole populations of patients at 1, 2, and 4 weeks, and on the new drug versus the standard drug. These interpretations are not within the individual, as one would make for a conditional analysis, coming up in Chapter 13.

Look at the estimate of the working correlation matrix. What does this tell you? In fact, if “comment out” the REPEATED statement and assume independent observations across individuals, i.e. $Y_{i1}, Y_{i2}, Y_{i3}$ independent, regression coefficients and standard errors change negligibly.
When to use which correlation structure $R(\alpha)$?

Because GENMOD automatically uses the “sandwich” estimate of the variance, adjusting the working correlation with an empirical (but yet model-based from mean estimates!) estimate of $\text{cov}(\hat{\beta})$, this GEE is robust to misspecification of $R(\alpha)$. However, it’s nice to have a formal tool for choosing.

Pan (2001) proposes a measure analogous to AIC for quasi-likelihood termed the QIC. When $\phi = 1$ it reduces to

$$QIC = -2L(\mu(\hat{\beta}); y_1, \ldots, y_n) + 2\text{trace}(\hat{\Omega}V_G),$$

where $\hat{\Omega} = \sum_{i=1}^{n} D_i'V_iD_i$; see Pan (2001).
QIC is automatically included in version 9.2 and above.

There are two versions: QIC and QIC_u.

QIC_u replaces 2\text{trace}(\hat{\Omega}V_G) with 2p and should only be used to choose among regression models (with fixed working correlation), whereas QIC can be used to choose among both regression models and working correlation structure...just use QIC to be safe.
Here’s my SAS code:

I am nesting the subject (case) index within both the drug sequence \(k = 1, \ldots, 6\) and pattern type \(p = 1, \ldots, 8\) for \((0, 0, 0), (0, 0, 1), \ldots, (1, 1, 1)\). The model looks like

\[
\text{logit } P(Y_{i(k*p)} = 1) = \gamma + \alpha_k + \beta_j,
\]

where \(\beta_3 = \alpha_6 = 0\) correspond to baseline.
11.5 Markov chains for transitional modeling

When \( j \) indexes time, \( Y_{i1}, Y_{i2}, \ldots, Y_{iT_i} \) is a stochastic process, often termed a *time series*. Let’s consider \( Y_{ij} = 0, 1 \) for now.

The series \( Y_{i1}, Y_{i2}, \ldots, Y_{iT_i} \) follows a first-order Markov chain if the distribution of \( Y_{ij} \) only cares about the previous value \( Y_{i,j-1} \), formally \( [Y_{ij} \mid Y_{i1}, \ldots, Y_{i,j-1}] = [Y_{ij} \mid Y_{i,j-1}] \).

Time-varying covariates can be included:

\[
\text{logit } P(Y_{ij} = 1 \mid Y_{i,j-1}) = \mathbf{x}_{ij}' \mathbf{\beta} + \gamma_1 Y_{i,j-1},
\]

where \( \gamma_1 \) models the effect of the \( i^{th} \) subject’s previous observation on the probability of a current (time \( j \)) success. \( e^{\gamma_1} \) has a nice interpretation in terms of how success odds changes based on what happened at last time point.
Second-order, and in general $t$-order, Markov chains can be considered by including the most previous $t$ observations $(Y_{i,j-1}, \ldots, Y_{i,j-t})$:

$$\text{logit } P(Y_{ij} = 1 | Y_{i,j-1}, \ldots, Y_{i,j-t}) = x_{ij}' \beta + \sum_{s=1}^{t} \gamma_s Y_{i,j-s}.$$ 

Interactions between covariates $x_{ij}$ and previous values can also improve model fit.
For a first order Markov-chain with no interaction the likelihood is written

$$\mathcal{L}(\beta) = \prod_{i=1}^{n} f_1(y_{i1}) f_2(y_{i2}|y_{i1}) f_3(y_{i3}|y_{i2}) \cdots f_{T_i}(y_{iT_i}|y_{i,T_i-1}).$$

if we ignore the marginal contribution of the first observation $f_1(y_{i1})$ we get

$$\mathcal{L}(\beta) = \prod_{i=1}^{n} f_2(y_{i2}|y_{i1}) f_3(y_{i3}|y_{i2}) \cdots f_{T_i}(y_{iT_i}|y_{i,T_i-1}).$$

For each subject $i$ we have the product of $T_i - 1$ conditional logistic regression kernels; the transitional model can be fit in PROC LOGISTIC as usual, but for observation $Y_{ij}$, treating $Y_{i,j-1}$ as an observed predictor!
Example (p. 476): Children were evaluated every year on whether they had a respiratory illness. A covariate of interest is whether the child’s mom smoked at the beginning of the study; \( s_i = 0 \) indicates not and \( s_i = 1 \) indicates a smoker.

Each child has a sequence of 4 indicators (\( Y_{i1}, Y_{i2}, Y_{i3}, Y_{i4} \)) taken at 7, 8, 9, and 10 years. For each child we have covariates \( s_i \) and \( t_j = j + 6 \). The first order Markov model is fit

\[
\text{logit } P(Y_{ij} = 1|Y_{i,j-1} = y_{i,j-1}) = \beta_0 + \beta_1 s_i + \beta_2 t_j + \beta_3 y_{i,j-1},
\]

for \( i = 1, \ldots, 537 \) and \( j = 2, 3, 4 \).

**Hosmer and Lemeshow Goodness-of-Fit Test**

Goodness-of-fit Statistic = 1.1723 with 6 DF (p=0.9782)

We see both time and whether the child had a respiratory illness the previous year are important predictors. Smoking is *almost* significant at the 5% level (and is significant if we perform a one-sided test). Maternal smoking increases the odds of a respiratory illness by about 34%. As time goes on the child is less likely to have a respiratory illness. If a child had a respiratory illness last year, the odds of having one this year are nine times greater than if the child did not have one last year.
