Logistic regression

Karl Gregory

2025-04-22

## Programming task data from Kutner et al. (2005)

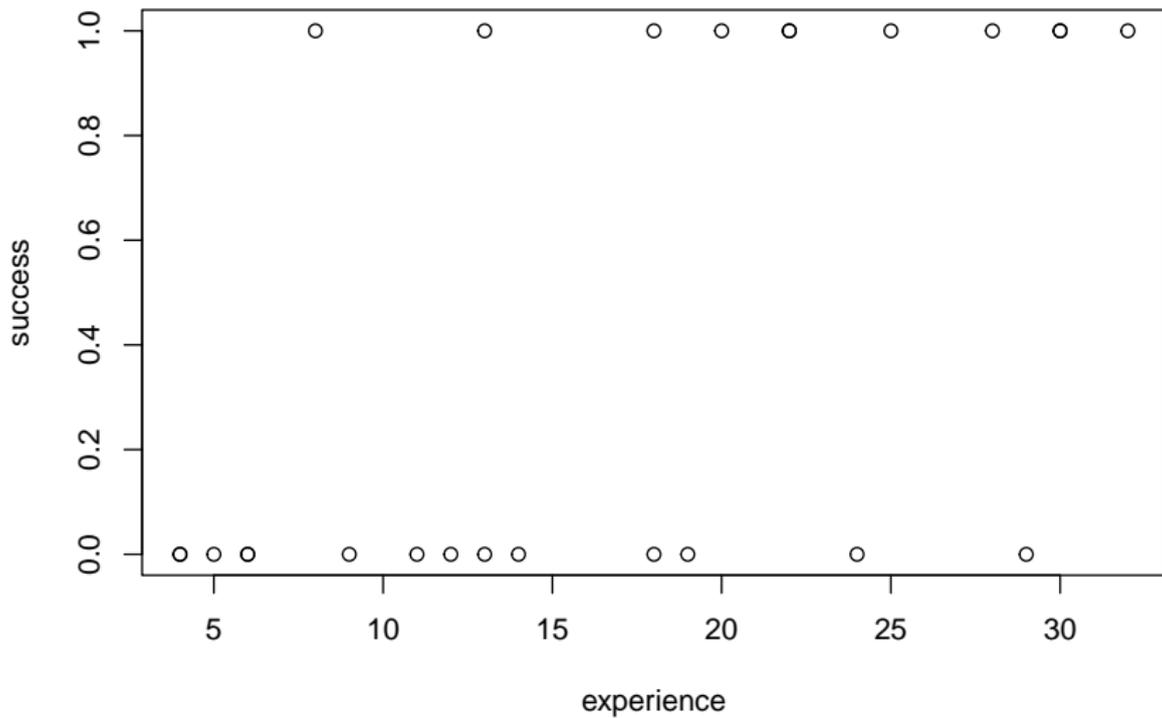

Twenty-five people succeeded or failed at a programming task.

Months of programming experience was recorded for each person.

```
experience <- c(14,29,6,25,18,4,18,12,22,6,30,11,30,5,20,13,9,32,24,13,19,4,28,22,8)
success <- c(0,0,0,1,1,0,0,0,1,0,1,0,1,0,0,1,0,1,0,0,1,0,1,1,1)
```

Can we predict probability of success based on experience?

```
plot(success ~ experience)
```

# Logistic regression model

Assume

$$Y_i \sim \text{Bernoulli}(\pi_i), \quad \log\left(\frac{\pi_i}{1 - \pi_i}\right) = \beta_0 + \beta_1 x_i,$$

for  $i = 1, \dots, n$ , where

- ▶  $Y_i$  is the response for observation  $i$ .
- ▶  $x_i$  is the value of a predictor/covariate/explanatory variable for obs  $i$ .
- ▶  $\pi_i$  is the probability of “success” for observation  $i$ .
- ▶  $\beta_0$  and  $\beta_1$  are slope and intercept parameters.
- ▶  $\pi_i/(1 - \pi_i)$  is the odds of “success” for obs  $i$ .
- ▶  $\log(\pi_i/(1 - \pi_i))$  is the log-odds for obs  $i$ .

Logistic regression assumes the log-odds are linear in the predictor.

# Odds

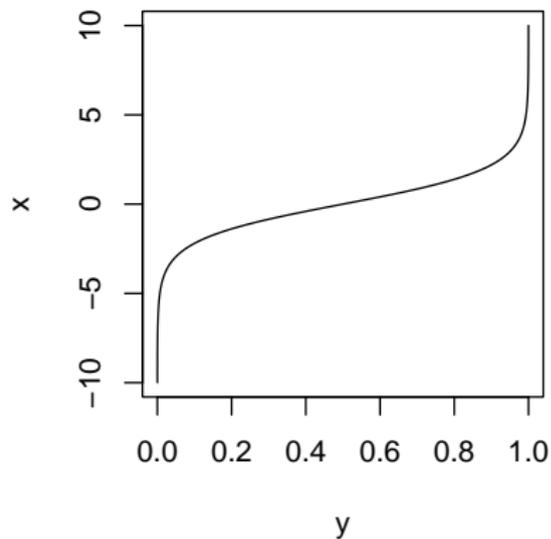

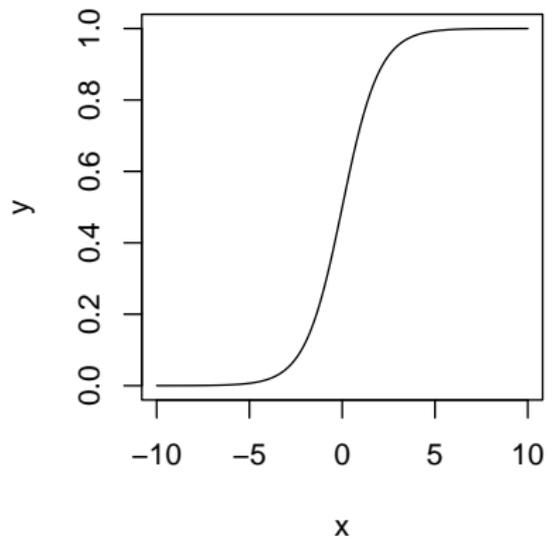

- ▶ Let  $\pi$  be the probability of success.
- ▶ Then  $\pi/(1 - \pi)$  is called the odds in favor of success.
  - a. If  $\pi = 1/2$  then  $\pi/(1 - \pi) = 1$ . “One-to-one” odds of success.
  - b. If  $\pi = 2/3$  then  $\pi/(1 - \pi) = 2$ . Success 2x more likely than failure.
  - c. If  $\pi = 1/4$  then  $\pi/(1 - \pi) = 1/3$ . Failure 3x more likely than success.

# The logit and logistic transformations

- ▶ The transformation  $y = \frac{e^x}{1+e^x}$  is called the logistic transformation.
- ▶ Its inverse  $x = \log\left(\frac{y}{1-y}\right)$  is called the logit transformation.
- ▶ We have

$$\log\left(\frac{\pi_i}{1-\pi_i}\right) = \beta_0 + \beta_1 x_i \iff \pi_i = \frac{e^{\beta_0 + \beta_1 x_i}}{1 + e^{\beta_0 + \beta_1 x_i}}$$

```
x <- seq(-10,10,length=200)
y <- exp(x) / (1 + exp(x))
par(mfrow= c(1,2))
plot(y~x,type = "l")
plot(x~y,type = "l")
```

# Goals in logistic regression

1. Estimate  $\beta_0$  and  $\beta_1$ .
2. Obtain fitted probabilities  $\hat{\pi}_1, \dots, \hat{\pi}_n$ .
3. Build CI for  $\beta_1$  and test  $H_0: \beta_1 = 0$ .
4. Give interpretations of the estimated regression coefficients.
5. Check goodness of fit of the logistic regression model.
6. Add additional covariates...

# Maximum likelihood estimation in logistic regression

- ▶ We do not use least-squares to estimate  $\beta_0$  and  $\beta_1$ .
- ▶ Instead we use maximum likelihood estimators (MLEs).
- ▶ The MLEs are the parameter values giving the observed data the highest possible probability.
- ▶ Intercept  $b_0$  and slope  $b_1$  give to the observed data the probability

$$\mathcal{L}_n(b_0, b_1) = \prod_{i=1}^n [\pi_i(b_0, b_1)]^{Y_i} [1 - \pi_i(b_0, b_1)]^{1-Y_i}$$

with  $\pi_i(b_0, b_1) = \frac{e^{b_0 + b_1 x_i}}{1 + e^{b_0 + b_1 x_i}}$  for  $i = 1, \dots, n$ .

- ▶ The MLEs  $\hat{\beta}_0, \hat{\beta}_1$  are the values of  $b_0, b_1$  that maximize  $\mathcal{L}_n(b_0, b_1)$ .
- ▶  $\mathcal{L}_n(b_0, b_1)$  is called the likelihood function.

## Computing the MLEs in logistic regression

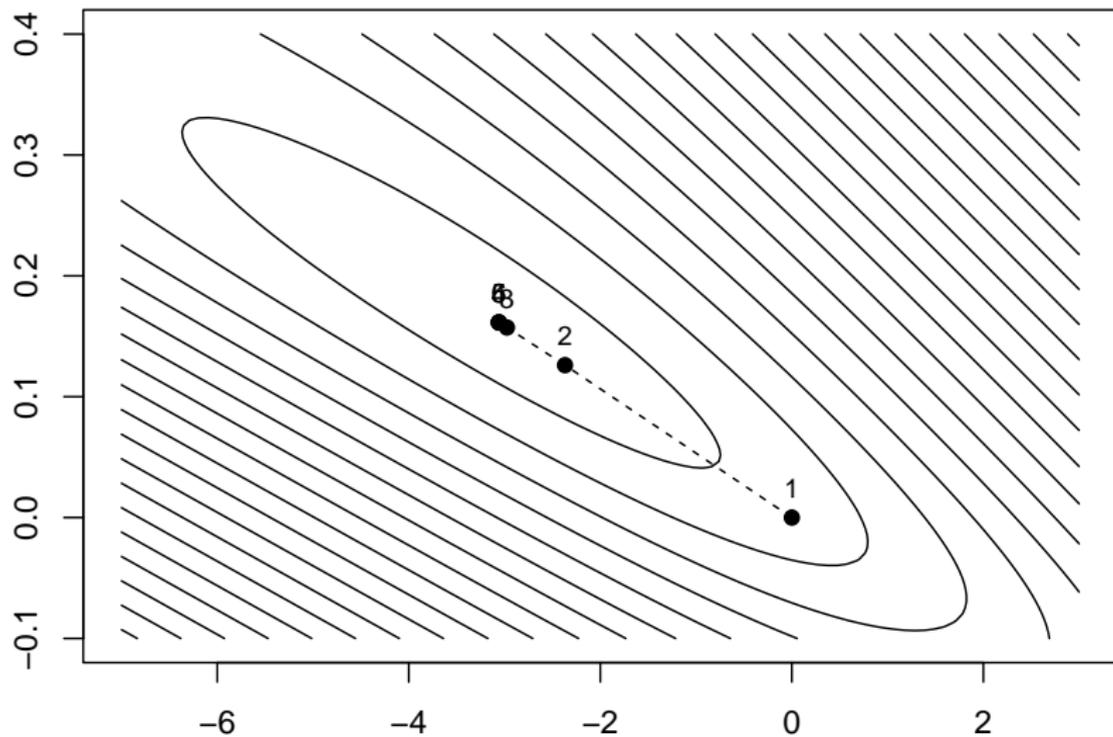

- ▶ There is no “closed-form” expression for  $\hat{\beta}_0$  and  $\hat{\beta}_1$ .
- ▶ One must find their values numerically, that is with an algorithm.
- ▶ More convenient to work with  $\log \mathcal{L}_n(b_0, b_1)$ , which is given by

$$\ell_n(b_0, b_1) = \sum_{i=1}^n [Y_i(b_0 + b_1 x_i) - \log(1 + e^{b_0 + b_1 x_i})].$$

- ▶ Newton's method is one way to find the maximizers of  $\ell_n(b_0, b_1)$ .

## Programming task data (cont)

Newton-Raphson algorithm for computing  $\hat{\beta}_0$  and  $\hat{\beta}_1$ .

# Generalized linear models

- ▶ The logistic regression model is in a class of models called GLMs.
- ▶ GLM stands for generalized linear model.
- ▶ Poisson regression, binomial response regression, i.a. are GLMs too.
- ▶ Use `glm()` function in R to obtain  $\hat{\beta}_0$  and  $\hat{\beta}_1$ .

Use `glm()` function with the option `family = "binomial"`.

```
glm_out <- glm(success ~ experience, family = "binomial")
summary(glm_out)
```

Call:

```
glm(formula = success ~ experience, family = "binomial")
```

Coefficients:

	Estimate	Std. Error	z value	Pr(> z )
(Intercept)	-3.05970	1.25935	-2.430	0.0151 *
experience	0.16149	0.06498	2.485	0.0129 *

---

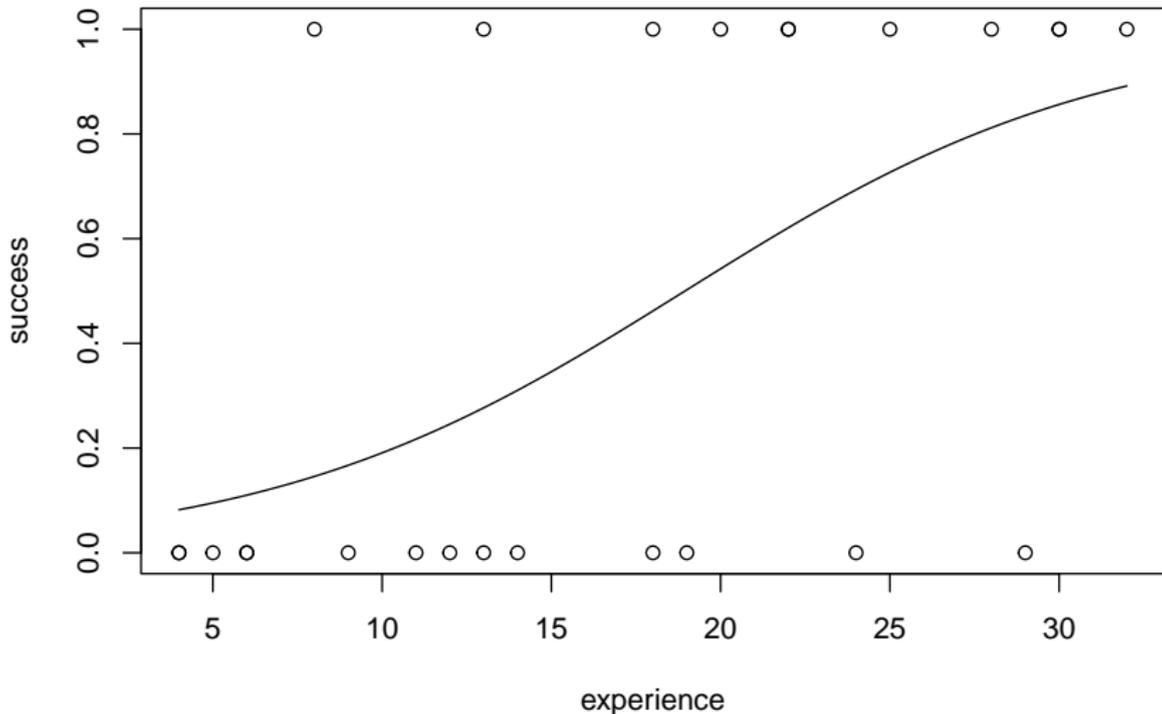

Signif. codes: 0 '\*\*\*' 0.001 '\*\*' 0.01 '\*' 0.05 '.' 0.1 ' ' 1

(Dispersion parameter for binomial family taken to be 1)

Null deviance: 34.296 on 24 degrees of freedom  
Residual deviance: 25.425 on 23 degrees of freedom  
AIC: 29.425

Number of Fisher Scoring iterations: 4

```
x <- seq(min(experience),max(experience),length = 200)
pihat_x <- 1/(1 + exp( -(coef(glm_out)[1] + coef(glm_out)[2]*x)))
plot(success ~ experience); lines(pihat_x~x)
```

## Fitted probabilities

- ▶ Define the fitted probabilities as

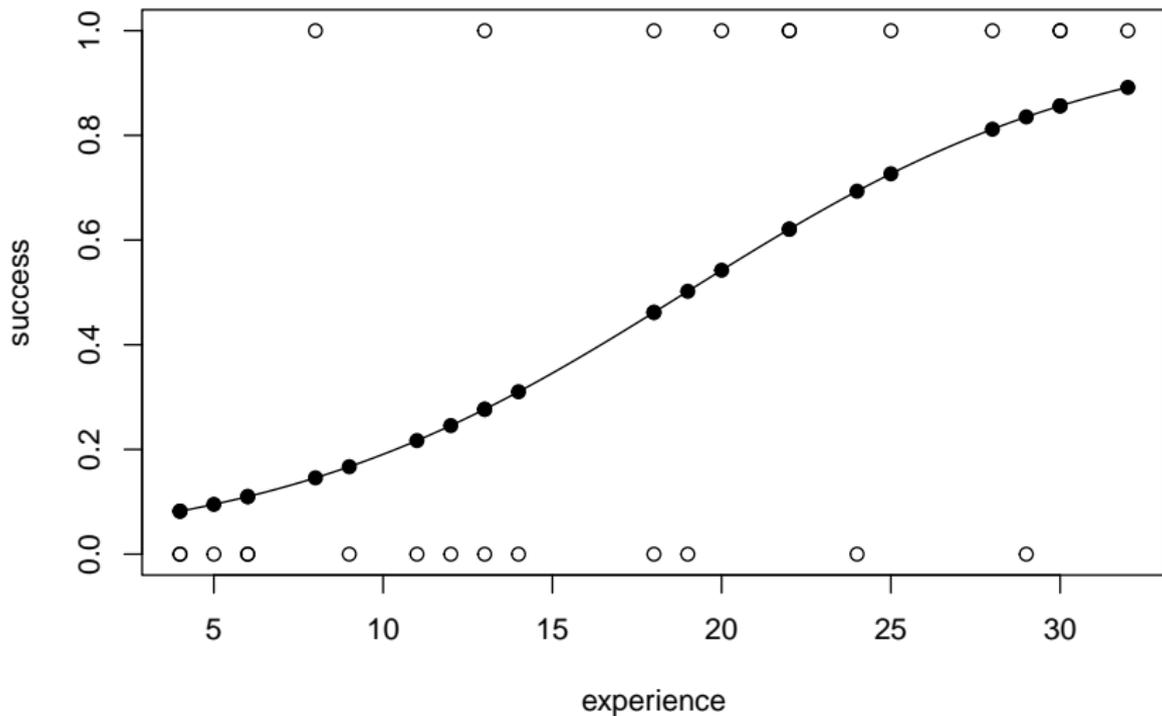

$$\hat{\pi}_i = \frac{e^{\hat{\beta}_0 + \hat{\beta}_1 x_i}}{1 + e^{\hat{\beta}_0 + \hat{\beta}_1 x_i}} \quad \text{for } i = 1, \dots, n.$$

- ▶ For any value  $x_{\text{new}}$ , we estimate the probability of “success” as

$$\hat{\pi}_{\text{new}} = \frac{e^{\hat{\beta}_0 + \hat{\beta}_1 x_{\text{new}}}}{1 + e^{\hat{\beta}_0 + \hat{\beta}_1 x_{\text{new}}}}.$$

## Programming task data (cont)

```
plot(success ~ experience); lines(pihat_x~x)  
points(glm_out$fitted.values~experience,pch = 19)
```

## Asymptotic distribution of slope estimator and CI

- ▶ For large enough  $n$ ,  $\hat{\beta}_1$  is approximately Normal, such that

$$\frac{\hat{\beta}_1 - \beta_1}{\widehat{\text{se}}\{\hat{\beta}_1\}} \underset{\text{approx}}{\sim} \text{Normal}(0, 1),$$

where, setting  $\hat{w}_i = \hat{\pi}_i(1 - \hat{\pi}_i)$  for  $i = 1, \dots, n$ , we may write

$$\widehat{\text{se}}\{\hat{\beta}_1\} = \left[ \sum_{i=1}^n \hat{w}_i x_i^2 - \left( \sum_{i=1}^n \hat{w}_i \right)^{-1} \left( \sum_{i=1}^n \hat{w}_i x_i \right)^2 \right]^{-\frac{1}{2}}.$$

- ▶ We can make an approximate  $(1 - \alpha)100\%$  CI for  $\beta_1$  as

$$\hat{\beta}_1 \pm z_{\alpha/2} \widehat{\text{se}}\{\hat{\beta}_1\}.$$

## Programming task data (cont)

```
# Confidence interval for beta1
pihat <- glm_out$fitted.values
bihat <- coef(glm_out)[2]
w <- pihat*(1-pihat)
se <- sqrt(1/(sum(w*experience^2) - sum(w*experience)^2/sum(w)))
lo <- bihat - 1.96 * se
up <- bihat + 1.96 * se
c(lo,up)
```

```
experience experience
0.03412491 0.28884692
```

```
# CIs for both beta0 and beta1 automatically from glm_out
confint.default(glm_out)
```

```
                2.5 %    97.5 %
(Intercept) -5.52797622 -0.5914155
experience   0.03412744  0.2888444
```

## Testing whether the slope coefficient is zero

To test  $H_0: \beta_1 = 0$  versus  $H_1: \beta_1 \neq 0$ , do:

1. Compute  $Z_{\text{test}} = \frac{\hat{\beta}_1}{\widehat{\text{se}}\{\hat{\beta}_1\}}$ .
2. Reject  $H_0$  at  $\alpha$  if  $|Z_{\text{test}}| > z_{\alpha/2}$ .
3. Obtain p value as  $2(1 - P(Z > |Z_{\text{test}}|))$ ,  $Z \sim \text{Normal}(0, 1)$ .

The `summary()` function on the `glm()` output prints this p value.

# Odds ratios

- ▶ Let  $\pi_0$  and  $\pi_1$  be success probs under an initial and an altered condition, respectively.

- ▶ Then we call the ratio

$$\frac{\pi_1/(1 - \pi_1)}{\pi_0/(1 - \pi_0)}$$

the odds ratio associated with the change from the initial to the altered condition.

- ▶ The odds ratio is the factor by which the odds are multiplied when the initial condition is changed to the altered condition.

## Interpreting the logistic regression parameters

▶ Let  $\pi_0$  and  $\pi_1$  be the “success” probabilities at  $x_0$  and  $x_0 + 1$ .

▶ Then we have the two equations

1.  $\log\left(\frac{\pi_0}{1-\pi_0}\right) = \beta_0 + \beta_1 x_0$

2.  $\log\left(\frac{\pi_1}{1-\pi_1}\right) = \beta_0 + \beta_1(x_0 + 1)$

▶ Subtracting the first equation from the second gives

$$\beta_1 = \log\left(\frac{\pi_1}{1-\pi_1}\right) - \log\left(\frac{\pi_0}{1-\pi_0}\right) = \log\left(\frac{\pi_1/(1-\pi_1)}{\pi_0/(1-\pi_0)}\right).$$

▶ The quantity  $\frac{\pi_1/(1-\pi_1)}{\pi_0/(1-\pi_0)}$  is called an odds ratio.

▶ So  $\beta_1$  is log of the odds ratio associated with a unit increase in  $x$ .

## Odds ratio from a unit increase in $x$

- ▶ From the previous slide, we have

$$e^{\beta_1} = \frac{\pi_1/(1 - \pi_1)}{\pi_0/(1 - \pi_0)}.$$

- ▶ Can build a CI for  $e^{\beta_1}$  by exponentiating the CI for  $\beta_1$ .
- ▶ Gives CI for  $e^{\beta_1}$  as  $[e^{\hat{\beta}_1 - z_{\alpha/2} \widehat{\text{se}}\{\hat{\beta}_1\}}, e^{\hat{\beta}_1 + z_{\alpha/2} \widehat{\text{se}}\{\hat{\beta}_1\}}]$ .
- ▶ A unit increase in  $x$  multiplies the odds of success by the factor  $e^{\beta_1}$ .
- ▶ What if the CI for  $e^{\beta_1}$  contains 1?

## Programming task data (cont)

```
exp(confint.default(glm_out,parm = "experience"))
```

```
                2.5 %   97.5 %  
experience 1.034716 1.334884
```

Each additional month of experience increases the odds of completing the programming task by a factor of 1.035 to 1.335, with 95% confidence.

## Residuals for logistic regression

- ▶ Ordinary residuals  $Y_i - \hat{\pi}_i$  cannot be Normally distributed.
- ▶ In GLMs, one looks at special residuals called deviance residuals.
- ▶ In logistic regression, the deviance residuals are defined as

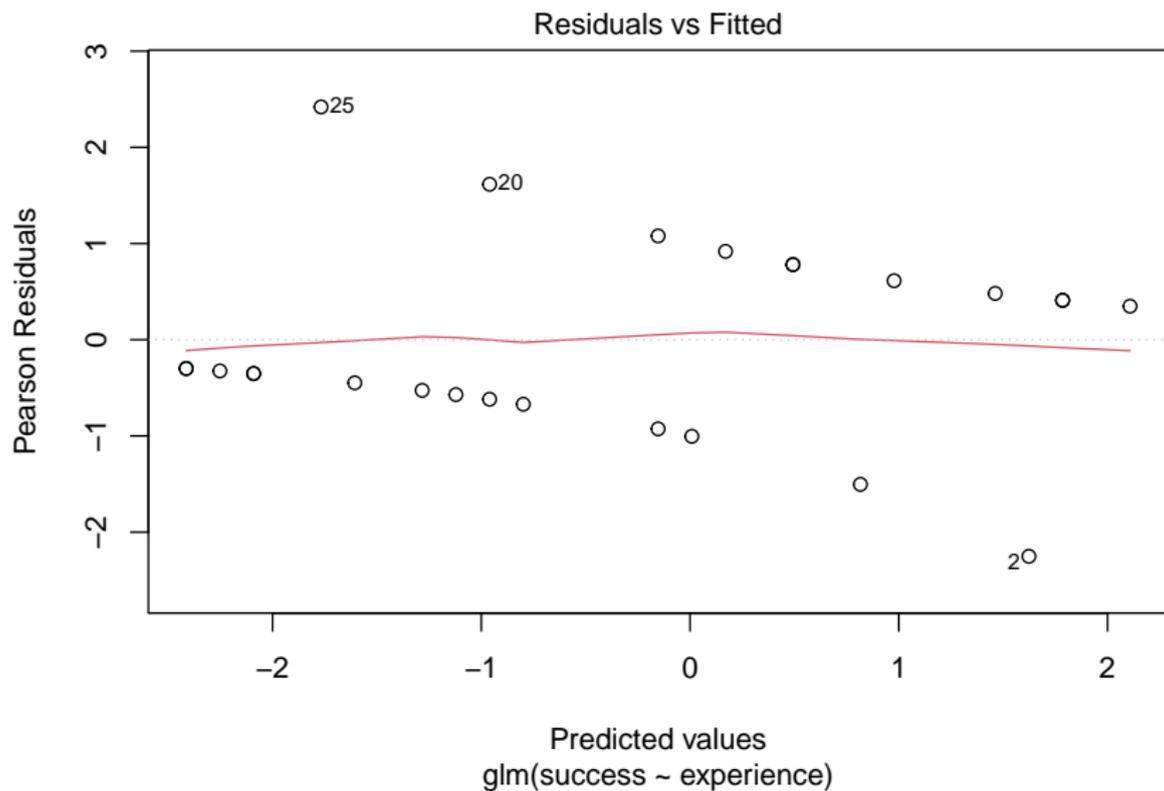

$$\hat{d}_i = \text{sign}(Y_i - \hat{\pi}_i) \sqrt{-2[Y_i \log \hat{\pi}_i + (1 - Y_i) \log(1 - \hat{\pi}_i)]}$$

for  $i = 1, \dots, n$ .

- ▶ These are not Normal either, but are useful for assessing model fit.

# Programming task data (cont)

```
plot(glm_out, which = 1)
```

## Checking model fit with a simulated envelope

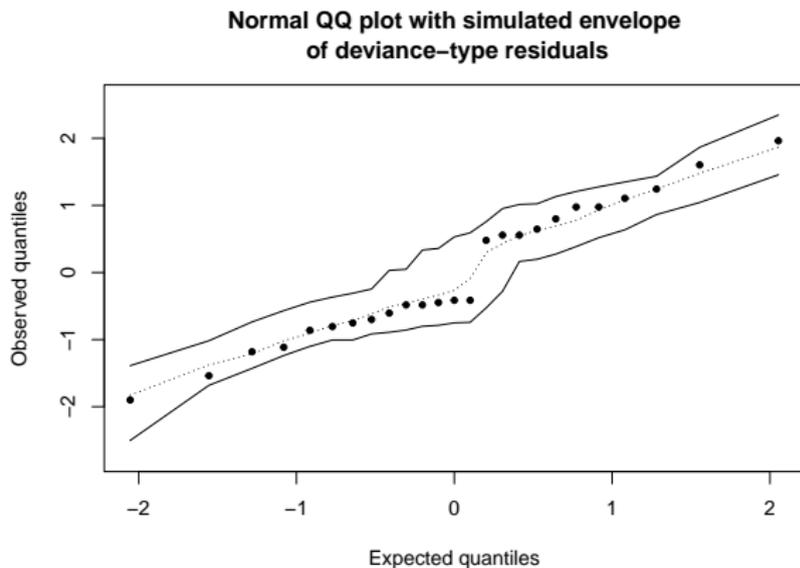

The simulated envelope method is described in Kutner et al. (2005):

- ▶ Fit the logistic regression model and obtain  $\hat{\pi}_1, \dots, \hat{\pi}_n$ .
- ▶ Obtain the deviance residuals; sort them as  $\hat{d}_{(1)} < \hat{d}_{(2)} < \dots < \hat{d}_{(n)}$ .
- ▶ Generate many new data sets  $Y_i^* \sim \text{Bernoulli}(\hat{\pi}_i)$ ,  $i = 1, \dots, n$ .
- ▶ For each new data set, obtain sorted  $\hat{d}_{(1)}^* < \hat{d}_{(2)}^* < \dots < \hat{d}_{(n)}^*$ .
- ▶ Plot  $\hat{d}_{(i)}$  as well as the 0.025 and 0.975 quantiles and the mean of the  $\hat{d}_{(i)}^* \forall i$  (it doesn't matter what is chosen as the  $x$ -axis).
- ▶ The quantiles of the  $\hat{d}_{(i)}^*$  make a band. If the model fits, then the  $\hat{d}_{(i)}$  should lie within the band and close to the mean.

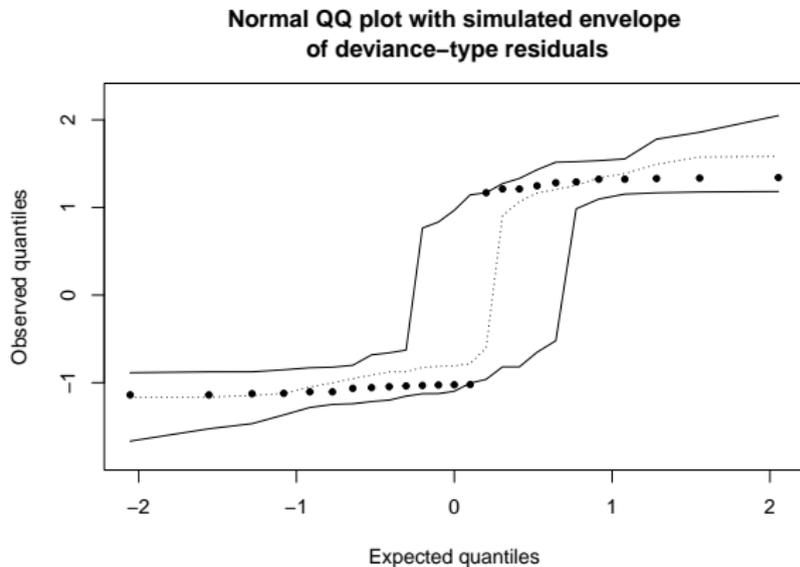

Asks: If the model is correct, how would the deviance residuals behave?

# Programming task data (cont)

```
library(glmtoolbox) # first time run install.packages("glmtoolbox")  
envelope(glm_out,type = "deviance")
```

```
experience2 <- (experience - mean(experience))^2
envelope(glm(success ~ experience2, family = "binomial"),type = "deviance")
```

# Logistic multiple regression model

Assume

$$Y_i \sim \text{Bernoulli}(\pi_i), \quad \log\left(\frac{\pi_i}{1 - \pi_i}\right) = \beta_0 + \beta_1 x_{i1} + \dots + \beta_p x_{ip},$$

for  $i = 1, \dots, n$ , where

- ▶  $Y_i$  is the response for observation  $i$ .
- ▶  $x_{i1}, \dots, x_{ip}$  are the values of the predictors for obs  $i$ .
- ▶  $\pi_i$  is the probability of “success” for observation  $i$ .
- ▶  $\beta_0$  is an intercept and  $\beta_1, \dots, \beta_p$  are slope parameters.
- ▶  $\pi_i/(1 - \pi_i)$  is the odds of “success” for obs  $i$ .
- ▶  $\log(\pi_i/(1 - \pi_i))$  is the log-odds for obs  $i$ .

So we assume the log-odds are a linear function of the predictors.

## Interpreting multiple logistic regression parameters

▶ Let  $\pi_{0j}$  and  $\pi_{1j}$  be the “success” probabilities at  $x_{0j}$  and  $x_{0j} + 1$  but with  $x_{0k}$  fixed for all  $k \neq j$ .

▶ Then we have the two equations

1.  $\log\left(\frac{\pi_{0j}}{1-\pi_{0j}}\right) = \beta_0 + \sum_{k \neq j} \beta_k x_{0k} + \beta_j x_{0j}$
2.  $\log\left(\frac{\pi_{1j}}{1-\pi_{1j}}\right) = \beta_0 + \sum_{k \neq j} \beta_k x_{0k} + \beta_j (x_{0j} + 1)$

▶ Subtracting the first equation from the second gives

$$\beta_j = \log\left(\frac{\pi_{1j}/(1-\pi_{1j})}{\pi_{0j}/(1-\pi_{0j})}\right) \quad \text{and} \quad e^{\beta_j} = \frac{\pi_{1j}/(1-\pi_{1j})}{\pi_{0j}/(1-\pi_{0j})}.$$

▶ So  $\beta_1$  is log of the odds ratio associated with a unit increase in  $x_j$  with all other predictors held fixed.

# German credit score data (cont)

Numeric predictors to encode the levels of the categorical predictor:

$$x_{i1} = \begin{cases} 1 & 200 \leq \text{checking} \\ 0 & \text{otherwise} \end{cases}$$

$$x_{i2} = \begin{cases} 1 & 0 \leq \text{checking} < 200 \\ 0 & \text{otherwise} \end{cases}$$

$$x_{i3} = \begin{cases} 1 & \text{no checking} \\ 0 & \text{otherwise} \end{cases}$$

Likewise for other categorical predictors.

## Deviances replace error sums of squares in GLMs

- ▶ The deviance is the sum of squared *deviance* residuals  $\sum_{i=1}^n \hat{d}_i^2$ .
- ▶ In logistic regression the deviance can be computed as

$$\text{Dev} = -2 \sum_{i=1}^n [Y_i \log \hat{\pi}_i + (1 - Y_i) \log(1 - \hat{\pi}_i)].$$

- ▶ Full-reduced model test: Reject  $H_0: \beta_j = 0$  for all  $j \in D$  if

$$\text{Dev}(\text{Reduced}) - \text{Dev}(\text{Full}) > \chi_{s,\alpha}^2,$$

where  $s$  is the number of predictors in  $D$  (need large  $n$ ).

## German credit score data (cont)

Test whether any level of checking status is important to the credit score.

```
credg_red <- credg[,-1] # remove checking_status column

glm_full <- glm(class ~ ., family = "binomial", data = credg)
glm_red <- glm(class ~ ., family = "binomial", data = credg_red)

p <- length(coef(glm_full)) - 1
s <- nlevels(credg$checking_status) - 1

1 - pchisq(glm_red$deviance - glm_full$deviance, s)
```

```
[1] 2.731149e-14
```

## Variable selection in logistic regression

- ▶ We may want to discard some of our predictors.
- ▶ One way is to add/remove variables stepwise according to AIC.
- ▶ Can do this just as we did in multiple linear regression.
- ▶ Be cautious about making inferences after selecting a model.

# German credit score data (cont)

```
glm_all <- glm(class ~ ., family = "binomial", data = credg)
step_back <- step(glm_all,
  direction = "backward",
  scope = formula(glm_all),
  criterion = "aic",
  trace = 0) # suppress printed output
summary(step_back)
```

Call:

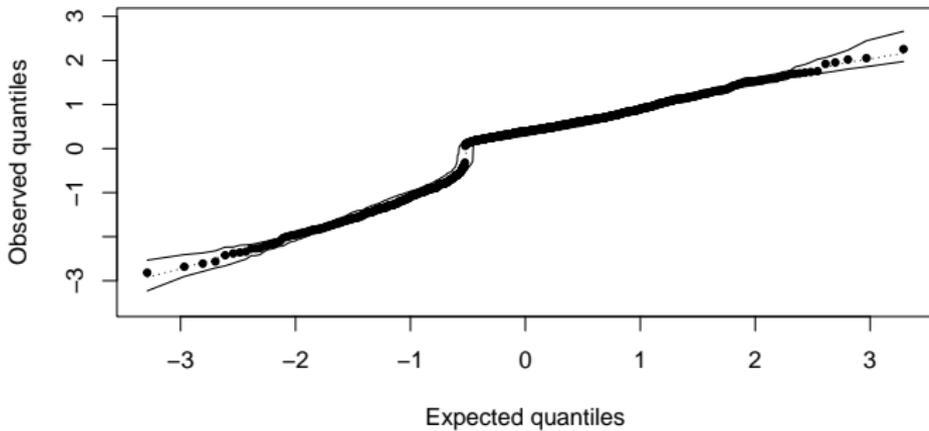

```
glm(formula = class ~ checking_status + duration + credit_history +
  purpose + credit_amount + savings_status + installment_commitment +
  personal_status + other_parties + age + other_payment_plans +
  housing + own_telephone + foreign_worker, family = "binomial",
  data = credg)
```

# Classification with the logistic regression model

Consider classifying the observations as 1 or 0 according to  $\hat{\pi}_i$ :

- ▶ Choose a threshold  $c \in [0, 1]$  and make the classification

$$\hat{Y}_i = \begin{cases} 1, & \hat{\pi}_i \geq c \\ 0, & \hat{\pi}_i < c. \end{cases}$$

- ▶ Can compute observed true positive and false positive rates

$$\text{TP} = \frac{\#\{\hat{Y}_i = 1 \cap Y_i = 1\}}{\#\{Y_i = 1\}}$$

$$\text{FP} = \frac{\#\{\hat{Y}_i = 1 \cap Y_i = 0\}}{\#\{Y_i = 0\}}.$$

- ▶ Plotting TP against FP over all  $c \in [0, 1]$  creates the receiver operating characteristic (ROC) curve.

## German credit score data (cont)

Compute TP and FP over a range of thresholds  $c$ . Plot ROC curve.

```
Y <- ifelse(credg$class == "good",1,0)
pi_hat <- step_back$fitted.values

n1 <- sum(Y == 1)
n0 <- sum(Y == 0)

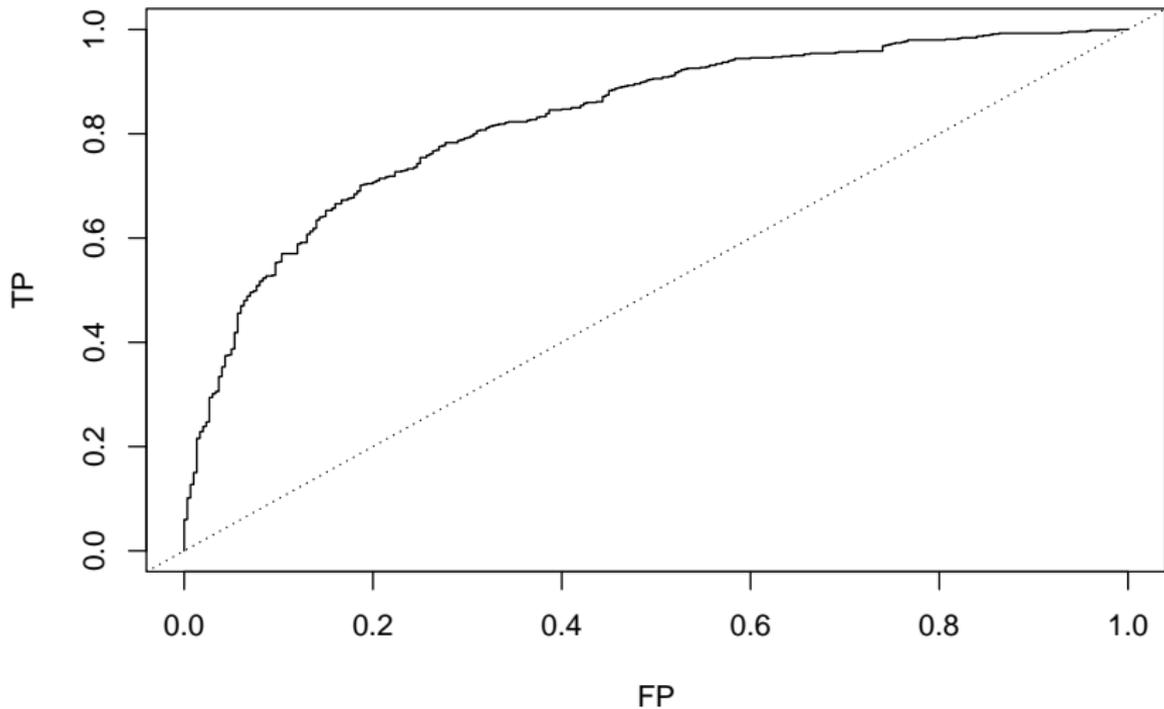

cc <- sort(c(0,pi_hat,1))
TP <- FP <- numeric(length(cc))
for(j in 1:length(cc)){

  Yhat <- pi_hat >= cc[j]
  TP[j] <- sum(Yhat == 1 & Y == 1) / n1
  FP[j] <- sum(Yhat == 1 & Y == 0) / n0

}
```

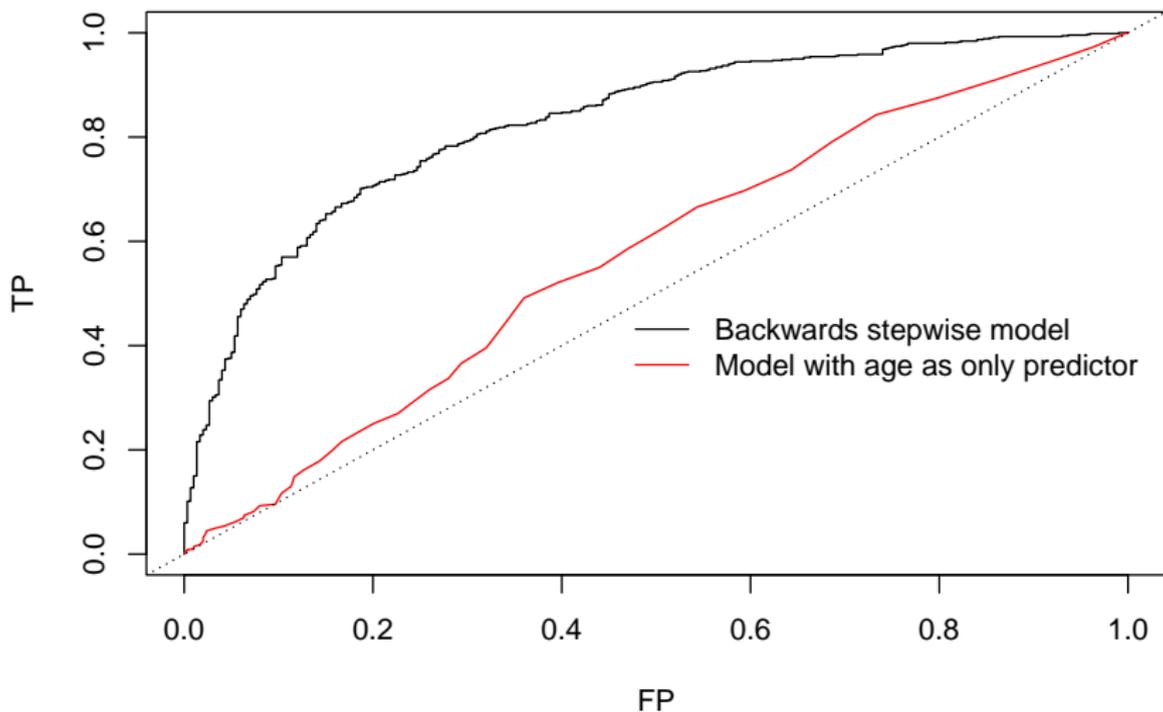

```
plot(TP ~ FP, type = "l", main = "ROC curve")  
abline(0,1,lty = 3)
```

ROC curve

Can use ROC curves to compare models. <sup>1</sup>

### ROC curves

<sup>1</sup>Best to evaluate model performance on a set of data not used in fitting the model.
